

AN AUTOMATED MEANS FOR STORING, DISPENSING AND ORIENTING
INJECTABLE DRUG VIALS FOR A ROBOTIC APPLICATION

Cross-Reference to Related Application

This application claims the benefit of U.S. patent application serial No. 60/430,481, filed December 3, 2002, and U.S. patent application serial No. 60/470,328, filed May 13, 2003, each of which is hereby incorporated by reference in its entirety.

Technical Field

The present invention relates generally to medical and pharmaceutical equipment, and more particularly, to an automated system for preparing a syringe to receive a unit dose of medication; dispensing the unit dose of medication from an injectable drug vial to the syringe; and to a feature that monitors and determines whether the injectable drug vial is in a proper orientation throughout one or more stations of the system.

Background

Disposable syringes are in widespread use for a number of different types of applications. For example, syringes are used not only to withdraw a fluid (e.g., blood) from a

patient but also to administer a medication to a patient. In the latter, a cap or the like is removed from the syringe and a unit dose of the medication is carefully measured and then injected or otherwise disposed within the syringe.

As technology advances, more and more sophisticated, automated systems are being developed for preparing and delivering medications by integrating a number of different stations, with one or more specific tasks being performed at each station. For example, one type of exemplary automated system operates as a syringe filling apparatus that receives user inputted information, such as the type of medication, the volume of the medication and any mixing instructions, etc. The system then uses this inputted information to disperse the correct medication into the syringe up to the inputted volume.

In some instances, the medication that is to be delivered to the patient includes more than one pharmaceutical substance. For example, the medication can be a mixture of several components, such as several pharmaceutical substances.

By automating the medication preparation process, increased production and efficiency are achieved. This results in reduced production costs and also permits the system to operate over any time period of a given day with only limited operator intervention for manual inspection to ensure proper operation is being achieved. Such a system finds particular utility in settings, such as large hospitals, including a large number of doses of medications that must be prepared daily. Traditionally, these doses have been prepared manually in what is an exacting but tedious responsibility for a highly skilled staff. In order to be valuable, automated systems must maintain the exacting standards set by medical regulatory organizations, while at

by first withdrawing the plunger 50 to a predetermined location, filling the chamber 30 with medication and then applying force against the flange 54 so as to move the plunger 50 forward within the chamber 30, resulting in a decrease in the volume of the chamber 30 and therefore causing the medication to be forced into and out of the barrel tip or luer 28.

If the medication needs to be reconstituted, the medication initially comes in a solid form and is contained in an injectable drug vial and then the proper amount of diluent is added and the vial is agitated to ensure that all of the solid goes into solution, thereby providing a medication having the desired concentration. The drug vial is typically stored in a drug cabinet or the like and is then delivered to other stations where it is processed to receive the diluent. When using automated devices, it is imperative that the vial be placed in its proper orientation at any given station since the processing of a vial that is not correctly orientated can lead to serious damage or the apparatus and the vial and the contents of the vial (medication) are likely lost. For example, during reconstitution and also during withdrawal of the medication from the vial, a needle or the like pierces through a septum of the vial to permit either a diluent to be injected therein or to permit the medication to be withdrawn from the vial. If the vial is orientated upside down, then the needle will strike the rigid bottom of the vial and this will lead to serious damage or destruction of the needle as well as the vial being potentially displaced and destroyed due to this striking action. During other processing operations, it is important for the vial to be correctly orientated in order to ensure that the overall operation runs smoothly and that no of the medication is wasted and that the costly equipment is not damaged.

What is needed in the art and has heretofore not been available is a system and method for automating the medication preparation process and more specifically, an automated system and method for preparing a syringe including the filling of medication therein and also a detector for determining whether an injectable drug vial (that contains the medication) is in a correct orientation.

SUMMARY

In one exemplary embodiment, an automated means for storing, dispensing and orienting injectable drug vials for a robotic application is provided and includes a plurality of automated syringe preparation stations is provided. The drug vial stores the medication that is either in solid form and thus needs to be reconstituted into the injectable drug or the vial can contain medication that was already been previously reconstituted and is ready for delivery to the syringe. The automated means includes a robotic vial gripper device for holding and transferring one vial from one station to a next station of the robotic application; and a detector that determines whether the vial is in a correct orientation throughout one or more stations of the robotic application.

In one embodiment, the robotic application is an automated medication preparation system that includes automated syringe preparation including reconstitution of the medication and delivery of the reconstituted medication to the syringe. The detector is configured to determine whether the vial is an upright position or is in an opposite downright position relative to ground. One exemplary type of detector is used in combination with a vial that includes a magnetic chip attached thereto at one end and the detector is capable of

detecting a change in a surrounding magnetic field such that when the vial is in a correct orientation, the magnetic chip of the vial influences the detector and causes it to generate a control signal indicating that the vial is in the correct orientation and can be advanced to a next station. If the vial is determined to not be in its proper orientation, the vial can simply be discarded.

In yet another embodiment, the vial has an optical marker and is used in combination with an optical detector that is capable of detecting the optical marker such that when the vial is in a correct orientation, the detector reads the optical marker of the vial and generates a control signal that indicates that the vial is in the correct orientation and can be advanced to a next station. Yet another suitable detector is one which acts as a reader and scans and reads a scannable tag (bar code) that is attached to the vial.

While the detector can be placed in any number of different locations and multiple detectors can be used, it is preferable for at least one detector to be positioned at a location prior to a station where medication contained in the vial is reconstituted using a cannula unit that includes a cannula extending therefrom that pierces a septum of a decapped vial or where reconstituted medication is simply withdrawn from the vial through the cannula. The present detectors overcome the deficiencies of the conventional arrangements and provide a system where the orientation of the vial is continuously monitored to ensure that processing of the vial can proceed without any risk or damage to any of the equipment.

Further aspects and features of the exemplary automated safety cap removal mechanism disclosed herein can be appreciated from the appended Figures and accompanying written description.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Fig. 2 is a schematic diagram illustrating one exemplary automated system, generally indicated at 100, for the preparation of a medication. The automated system 100 is divided into a number of stations where a specific task is performed based on the automated system 100 receiving user input instructions, processing these instructions and then preparing unit doses of one or more medications in accordance with the instructions. The automated system 100 includes a station 110 where medications and other substances used in the preparation process are stored. As used herein, the term “medication” refers to a medicinal preparation for administration to a patient. Often, the medication is initially stored as a solid, e.g., a powder, to which a diluent is added to form a medicinal composition. Thus, the station 110 functions as a storage unit for storing one or medications, etc. under proper storage conditions. Typically, medications and the like are stored in sealed containers, such as vials, that are labeled to clearly indicate the contents of each vial.

A first station 120 is a syringe storage station that houses and stores a number of syringes. For example, up to 500 syringes or more can be disposed in the first station 120 for storage and later use. The first station 120 can be in the form of a bin or the like or any other type of structure than can hold a number of syringes. In one exemplary embodiment, the syringes are provided as a bandolier structure that permits the syringes to be fed into the other components of the system 100 using standard delivery techniques, such as a conveyor belt, etc.

The system 100 also includes a rotary apparatus 130 for advancing the fed syringes from and to various stations of the system 100. A number of the stations are arranged

circumferentially around the rotary apparatus 130 so that the syringe is first loaded at the first station 120 and then rotated a predetermined distance to a next station, etc. as the medication preparation process advances. At each station, a different operation is performed with the end result being that a unit dose of medication is disposed within the syringe that is then ready to be administered.

One exemplary type of rotary apparatus 130 is a multiple station cam-indexing dial that is adapted to perform material handling operations. The indexer is configured to have multiple stations positioned thereabout with individual nests for each station position. One syringe is held within one nest using any number of suitable techniques, including opposing spring-loaded fingers that act to clamp the syringe in its respective nest. The indexer permits the rotary apparatus 130 to be advanced at specific intervals.

At a second station 140, the syringes are loaded into one of the nests of the rotary apparatus 130. One syringe is loaded into one nest of the rotary apparatus 130 in which the syringe is securely held in place. The system 100 preferably includes additional mechanisms for preparing the syringe for use, such as removing a tip cap and extending a plunger of the syringe at a third station 150. At this point, the syringe is ready for use.

The system 100 also preferably includes a reading device (not shown) that is capable of reading a label disposed on the sealed container containing the medication. The label is read using any number of suitable reader/scanner devices, such as a bar code reader, etc., so as to confirm that the proper medication has been selected from the storage unit of the station 110. Multiple readers can be employed in the system at various locations to confirm the accuracy of the entire process. Once the system 100 confirms that the sealed container that

has been selected contains the proper medication, the container is delivered to a fourth station 160 using an automated mechanism, such a robotic gripping device as will be described in greater detail. At the fourth station 160, the vial is prepared by removing the safety cap from the sealed container and then cleaning the exposed end of the vial. Preferably, the safety cap is removed on a deck of the automated system 100 having a controlled environment. In this manner, the safety cap is removed just-in-time for use.

The system 100 also preferably includes a fifth station (fluid transfer station) 170 for injecting or delivering a diluent into the medication contained in the sealed container and then subsequently mixing the medication and the diluent to form the medication composition that is to be disposed into the prepared syringe. At this fluid transfer station, the prepared medication composition is withdrawn from the container (i.e., vial) and is then delivered into the syringe. For example, a cannula can be inserted into the sealed vial and the medication composition then aspirated into a cannula set. The cannula is then withdrawn from the vial and is then rotated relative to the rotary apparatus 130 so that it is in line with (above, below, etc.) the syringe. The unit dose of the medication composition is then delivered to the syringe, as well as additional diluent if necessary or desired. The tip cap is then placed back on the syringe at a sixth station 180. A seventh station 190 prints and station 195 applies a label to the syringe and a device, such as a reader, can be used to verify that this label is placed in a correct location and the printing thereon is readable. Also, the reader can confirm that the label properly identifies the medication composition that is contained in the syringe. The syringe is then unloaded from the rotary apparatus 130 at an unloading station 200 and delivered to a predetermined location, such as a new order bin, a conveyor, a sorting device,

or a reject bin. The delivery of the syringe can be accomplished using a standard conveyor or other type of apparatus. If the syringe is provided as a part of the previously-mentioned syringe bandolier, the bandolier is cut prior at a station 198 located prior to the unloading station 200.

Figs. 3 through 15 illustrate parts of the third station 150 for preparing a syringe, the fluid transfer station 170, and the sixth station 180 for preparing the syringe for later use. In other words, Figs. 3-15 illustrate in more detail the stations and automated devices that are used in removal of the tip cap 40 from the barrel tip 28, the filling of barrel chamber 30 with medication and the replacement of the tip cap 40 on the barrel tip 28. Fig. 3 is a perspective view of an automated device 300 that removes the tip cap 40 from the barrel tip 28 as the syringe 10 is prepared for receiving a prescribed dose of medication as part of the third station 150 of the automated medication preparation system 100. The device 300 is a controllable device that is operatively connected to a control unit, such as a computer, which drives the device 300 to specific locations at selected times. The control unit can be a personal computer that runs one or more programs to ensure coordinated operation of all of the components of the system 100. The device 300 and other suitable devices described in greater detail in U.S. Serial No. 10/426,910, which is hereby incorporated by reference in its entirety.

As previously mentioned, one exemplary rotary device 130 is a multiple station cam-indexing dial that is adapted to perform material handling operations. The dial 130 has an upper surface 132 and first and second retaining members 134, 136 for securely holding one syringe 10 in a releasable manner. More specifically, the first retaining member 134 locates the barrel 20 near the distal end 24 thereof and the second retaining member 136 grips and

holds the barrel 20 near the proximal end 22 thereof. One exemplary first retaining member 134 includes an arm 135 that is integral to the upper surface 132 of the rotary device 130 and extends outwardly from a main peripheral edge 137 of the dial. The arm 135 has a notch 139 formed at a distal end thereof that is complementary in shape and size to the outer surface of the syringe 10 so that the syringe barrel 20 is received and held within the notch 139. The notch 139 is defined by a pair of opposing fingers 141, with the notch 139 being formed therebetween. The notch 139 is thus V-shaped in this exemplary embodiment.

The second retaining member 136 is configured to hold and retain the proximal end 22 of the barrel 20. The second retaining member 136 includes operable pivotable arms 143, 145 that pivot between an open position where the syringe 10 is free to be removed from the dial 130 and a closed position in which the syringe 10 is securely held on the dial 130. A shaped surface 151 also forms a part of the retaining member 136 and is disposed behind the pivotable arms 143, 145. The syringe 10 is disposed between the pivotable arms 143, 145 and the surface 151 and in the retained position, the pivotable arms 143, 145 are in the closed position and the syringe 10 is held securely between the pivotable arms 143, 145 and the surface 151. As will be described in greater detail hereinafter, the controller directs the pivotable arms 143, 145 to either the open or closed positions.

A post 161 is provided for holding the tip cap 40 after its removal to permit the chamber 30 to be filled with medication. One exemplary post 161 has a circular cross-section and is formed near or at the interface between the arm 135 and the dial 130. The post 161 can also be formed on the upper surface 132 of the dial 130. Thus, the precise location of the post 161 can vary so long as the post 161 is located where the tip cap 40 can sit without interfering

with the operation of any of the automated devices and also the post 161 should not be unnecessarily too far away from the held syringe 10 since it is desired for the automated devices to travel a minimum distance during their operation to improve the overall efficiency of the system 100. The specific shape of the post 161 can likewise vary so long as the post 161 can hold the tip cap 40 so that it remains on the post 161 during the rotation of the dial 130 as the associated syringe 10 is advanced from one station to another station.

While in one exemplary embodiment, the syringes 10 are fed to the rotary device 130 as part of a syringe bandolier (i.e., multiple syringes 10 are disposed in series and interconnected by a web), it will be appreciated that the syringes 10 can be fed to the rotary device 130 in any number of other ways. For example, the syringes 10 can be fed individually into the rotary device 130 from a loose supply of syringes 10.

The automated device 300 is a robotic device and preferably, the automated device 300 is a linear actuator with a gripper. The device 300 has a vertical base 310 which is adjustable in at least several directions. For example, the vertical base 310 has an independent reach (y axis) and vertical axis (x axis) which provides part of the flexibility and motion control that is desirable for the device 300. The vertical base 310 has an upper end 312 and an opposing lower end 314 which is operatively coupled to other movable components to permit the vertical base 310 to move in an up/down direction along the x axis and in lateral directions along the y axis. The upper end 312 is connected to a horizontal support member 320 that extends outwardly away from the vertical base 310. In one exemplary embodiment, the lower end 314 is disposed between two support beams that are part of a robotic device and are moved in a number of different directions, including along the x axis and the y axis.

A block member 330 is connected to the horizontal support member 320 and more specifically, the block member 330 is disposed on an underside of the horizontal support member 320 so that it is spaced away from the vertical base 310. The exemplary block member 330 has a block-like shape and is connected to the underside of the horizontal support member 320 by one or more connectors that can be in the form of support columns, etc.

The device 300 has first and second positionable gripping arms 340, 350 which are adjustable in at least one direction and which are coupled to and extend downwardly from the block member 330. For example, each of the gripping arms 340, 350 is movable at least in a direction along the y axis which provide the flexibility and motion control that is desirable in the present system 100. The gripping arms 340, 350 are programmed to work together in tandem so that both arms 340, 350 are driven to the same location and the same time.

The block member 330 can house some of the electronic components and the like that permit the gripping arms 340, 350 to move between the open and closed positions. The coupling between the block member 330 and the gripping arms 340, 350 is such that the gripping arms 340, 350 have the necessary degree of movement to permit the opening and closing thereof.

Each of the gripping arms 340, 350 is a generally L-shaped member that is formed of a vertical section 342 and a horizontal gripping section 344 that extends outwardly from one end of the vertical section 342. The gripping section 344 has a cut-out or notch 360 formed therein for receiving and gripping a section of the tip cap 40 of the syringe 10. Accordingly, the notch 360 has a complementary shape as the shape of the tip cap 40. One exemplary notch 360 has a generally semi-circular shape and it seats against approximately $\frac{1}{2}$

the gripping arms 340, 350 are disposed around the tip cap 40. In other words, the tip cap 40 is disposed between the gripping section 344 of the opposing arms 340, 350 and more specifically, the gripping sections 344 are disposed adjacent the base section 41 of the tip cap 40 underneath the flange 43 with the notches 360 being aligned with the outer surface of the base section 41. An actuator or the like of the device 300 is then activated causing the gripping arms 340, 350 to move inwardly toward one another until the gripping sections 344 seat against the outer surface of the base section 41 of the tip cap 40. In this closed position, the gripping arms 340, 350 apply a force against the base section 41 so that the tip cap 40 is securely held by the gripping sections 344. When the gripping arms 340, 350 are driven to the closed position, the gripping sections 344 seat against one another and the notches 360 align such that the gripping sections 344 substantially encircle the base section 41.

The apparatus 300 can be driven in any number of different ways that are known and suitable for this intended use. For example, the apparatus 300 can be pneumatically based according to one exemplary embodiment and as shown in Fig. 3. In this embodiment, a number of pneumatic conduits are provided for moving the gripping arms 340, 350.

After the tip cap 40 is nested within the gripping sections 344, the control unit 370 directs the vertical base 310 upward and this motion causes the tip cap 40 to be displaced from the barrel tip 28 as shown in phantom in Fig. 5. After the tip cap 40 is freed from the barrel tip 28, it remains held between the gripping sections 344 of the opposing arms 340, 350. The vertical base 310 is then driven more inward, as indicated by arrow 311, toward the dial 130 until the held tip cap 40 is positioned over the post 161. Once the tip cap 40 is disposed

over the post 161, the controller 370 instructs the vertical base 310 to move downwardly so that the post 161 is disposed within a hollow interior of the tip cap 40. The actuator is then activated causing the gripping arms 340, 350 to move to the open position, thereby releasing the tip cap 40 as shown in Fig. 5. Because the tip cap 40 sits on the post 161, its movement is restricted after the gripping arms 340, 350 release their gripping action therefrom and the tip cap 40 remains seated on the post 161 as the rotary device 130 advances to deliver the uncapped syringe 10 to another station. The device 300 then is returned to its initial position, the dial 130 is advanced and the operation is repeated with the device 300 gripping and removing one tip cap 40 from the next capped syringe 10.

Now referring to Figs. 6-8, the system 100 also includes a device 400 for extending the plunger 50 of one uncapped syringe 10 after it has had its tip cap 40 removed therefrom. For ease of illustration, the device 400 as well as the device 300 are described as being part of the third station 150 of the system 100. The device 400 extends the plunger 50 so that the syringe 10 can receive a desired dose based upon the particular syringe 10 being used and the type of application (e.g., patient's needs) that the syringe 10 is to be used for. The device 400 can have any number of configurations so long as it contains a feature that is designed to make contact with and withdraw the plunger 50. In one exemplary embodiment, the automated device 400 is a robotic device and preferably, the automated device 400 is a linear actuator with a gripper. For example, one exemplary device 400 is a mechanical device that has a movable gripper 410 that includes a gripping edge 420 that engages the flange 54 of the plunger 50, as shown in Fig. 7, and then the gripper 410 is moved in a downward direction causing the plunger 50 to be moved a predetermined amount as shown in Fig. 8. For example,

the gripper 410 can be the part of an extendable/retractable arm that includes the gripping edge 420 for engaging the syringe 10 above the plunger flange 54. When an actuator or the like causes the gripper 410 to move in a downward direction, the gripping edge 420 seats against the flange 54 and further movement of the gripper 410 causes the extension of the plunger 50. Once the plunger 50 has been extended the prescribed distance, the gripper 410 moves laterally away from the plunger 50 so that the interference between the flange 54 of the plunger 50 and the gripping edge 420 no longer exists. In other words, the gripper 410 is free of engagement with the plunger 50 and can therefore be positioned back into its initial position by being moved laterally and/or in an up/down direction (e.g., the gripper 410 can move upward to its initial position). Another exemplary plunger extending device is described in commonly assigned U.S. patent application serial No. 10/457,066, which is hereby incorporated by reference in its entirety.

Thus, the device 400 complements the device 300 in getting the syringe 10 ready for the fluid transfer station at which time, a prescribed amount of medication is dispensed into the chamber 30 of the barrel 20 as will be described in greater detail hereinafter.

The device 400 is part of the overall programmable system and therefore, the distance that the gripper 410 corresponds to a prescribed movement of the plunger 50 and a corresponding increase in the available volume of the chamber 30 of the barrel 20. For example, if the prescribed unit dose for a particular syringe 10 is 8 ml, then the controller instructs the device 400 to move the gripper 410 a predetermined distance that corresponds

gripper device that can capture and remove the vial 60 from the pedestal before it is delivered to the next processing station. The central control has a database that stores all the identifying information for the vials 60 and therefore, when a dose is being prepared, the controller knows which vial (by its identifying information) is to be delivered from the cabinet 110 to the pedestal 520. If the scanning process and other safety features does not result in a clear positive identification of the vial as compared to the stored identifying information, then the vial is automatically discarded and the controller will instruct the system to start over and retrieve a new vial.

If the vial 60 is identified as being the correct vial, then a vial gripper device 530 moves over to the pedestal for retrieving the vial 60. The vial gripper device 530 is configured to securely grip and carry the vial in a nested manner to the next stations as the drug is prepared for use. For example, the device 530 can include a vertical base 532 that is operatively coupled to a moveable base portion 534 that can ride within tracks to permit the device 530 to move not only in forward-rearward directions but also in a side-to-side manner. At a distal end of the vertical base 532, a gripper unit 540 is provided and is operatively coupled to the vertical base 532 so that the gripper unit 540 can move in an up-and-down direction. For example, the gripper unit 540 can be pneumatically supported on the vertical base 532 so that activation of the pneumatic mechanism causes either up or down movement of the gripper unit 540 relative to the vertical base 532. The gripper unit 540 includes a pair of grippers or arms 542 that are positionable between closed and open positions with the vial 60 being captured between the arms 542 in the closed position in such a manner that the vial 60 can be securely moved and even inverted and shaken without concern that the vial 60 will

a wick saturated with a cleaning solution, such as an alcohol. The exposed area of the vial 60 is cleaned by making several passes over the saturated wick which contacts and baths the exposed area with cleaning solution. After the vial 60 is cleaned at the station 560, the gripper unit 540 rotates so that the vial 60 is returned to its upright position and remains held between the gripper arms 542.

The device 530 then advances forward to a fluid transfer station 570. The fluid transfer station 570 is an automated station where the medication (drug) can be processed so that it is in a proper form for injection into one of the syringes 10 that is coupled to the rotary dial 130. When the vial 60 contains only a solid medication and it is necessary for a diluent (e.g., water or other fluid) to be added to liquify the solid, this process is called a reconstitution process. Alternatively and as will be described in detail below, the medication can already be prepared and therefore, in this embodiment, the fluid transfer station is a station where a precise amount of medication is simply aspirated or withdrawn from the vial 60 and delivered to the syringe 10.

For purpose of illustration, the reconstitution process is first described. After having been cleaned, the vial 60 containing a prescribed amount of solid medication is delivered in the upright position to the fluid transfer station 570 by the device 530 as shown in Fig. 14. As will be appreciated, the device 530 has a wide range of movements in the x, y and z directions and therefore, the vial 60 can easily be moved to a set fluid transfer position. At this position, the vial 60 remains upright and a fluid transfer device 580 is brought into position relative to the vial 60 so that a fluid transfer can result therebetween. More specifically, the fluid transfer device 580 is the main means for both discharging a precise

amount of diluent into the vial 60 to reconstitute the medication and also for aspirating or withdrawing the reconstituted medication from the vial 60 in a precise, prescribed amount. The device 580 is a controllable device that is operatively connected to a control unit, such as a computer, which drives the device 580 to specific locations at selected times. The control unit can be a personal computer that runs one or more programs to ensure the coordinated operation of all of the components of the system 100.

As illustrated in Figs. 2 and 9-20, one exemplary fluid transfer device 580 includes a vertical base section 582 that is rotatably mounted to a base 584 so that the device 580 can rotate between the fluid transfer position to the rotary device 130 where the medication is discharged into the syringes 10. The base 584 can be mounted so that it can move in both the x and y directions. Near a distal end of the base 584, a rotatable cannula unit 590 is operatively and rotatably coupled to the base 584 to permit the cannula unit 590 a degree of rotation relative to the base 584. For example, the cannula unit 590 can include a vertical housing 592 that is rotatably coupled to the base 584 between the ends thereof. At an upper end 594 of the housing 592, a cannula housing 600 is operatively coupled thereto such that the cannula housing 600 can be independently moved in a controlled up and down manner so to either lower it or raise it relative to the vial 60 in the fluid transfer position. For example, the cannula housing 600 can be pneumatically operated and therefore can include a plurality of shafts 602 which support the cannula housing 600 and extend into an interior of the vertical housing 592 such that when the device is pneumatically operated, the shafts 602 can be driven either out of or into the housing 592 resulting in the cannula housing 600 either being raised or lowered, respectively, as shown in Figs. 14 and 15.

At one end of the cannula housing 600 opposite the end that is coupled to the vertical housing 592, the cannula housing 600 includes a cannula 610. The cannula 610 has one end 612 that serves to pierce the septum of the vial 60 and an opposite end 614 that is connected to a main conduit 620 that serves to both deliver diluent to the cannula 610 and ultimately to the vial 60 and receive aspirated medication from the vial 60. Preferably, the cannula 610 is of the type that is known as a vented cannula which is vented to atmosphere as a means for eliminating any dripping or spattering of the medication during an aspiration process. More specifically, the use of a vented needle to add (and withdraw) the fluid to the vial overcomes a number of shortcomings associated with cannula fluid transfer and in particular, the use of this type of needle prevents backpressure in the vial (which can result in blow out or spitting or spraying of the fluid through the piercing hole of the cannula). The venting takes place via an atmospheric vent that is located in a clean air space and is formed in a specially designed hub that is disposed over the needle. By varying the depth that the needle penetrates the vial, the user can control whether the vent is activated or not. It will be appreciated that the venting action is a form of drip control (spitting) that may otherwise take place.

Moreover, the cannula 610 is also preferably of the type that is motorized so that the tip of the cannula 610 can move around within the vial 60 so that cannula 610 can locate and aspirate every last drop of the medication. In other words, the cannula 610 itself is mounted within the cannula unit 590 so that it can move slightly therein such that the tip moves within the vial and can be brought into contact with the medication wherever the medication

may lie within the vial 60. Thus, the cannula 610 is driven so that it can be moved at least laterally within the vial 60.

An opposite end of the main conduit 620 is connected to a fluid pump system 630 that provides the means for creating a negative pressure in the main conduit 620 to cause a precise amount of fluid to be withdrawn into the cannula 610 and the main conduit 620 as well as creating a positive pressure in the main conduit 620 to discharge the fluid (either diluent or medication) that is stored in the main conduit 620 proximate the cannula 610. In the illustrated embodiment, the fluid pump system 630 includes a first syringe 632 and a second syringe 634, each of which has a plunger or the like 638 which serves to draw fluid into the syringe or expel fluid therefrom. The main difference between the first and second syringes 632, 634 is that the amount of fluid that each can hold. In other words, the first syringe 632 has a larger diameter barrel and therefore has increased holding capacity relative to the second syringe 634. As will be described in detail below, the first syringe 632 is intended to receive and discharge larger volumes of fluid, while the second syringe 634 performs more of a fine tuning operation in that it precisely can receive and discharge small volumes of fluid.

The syringes 632, 634 are typically mounted so that an open end 636 thereof is the uppermost portion of the syringe and the plunger 638 is disposed so that it is the lowermost portion of the syringe. Each of the syringes 632, 634 is operatively connected to a syringe driver, generally indicated at 640, which serves to precisely control the movement of the plunger 638 and thus precisely controls the amount (volume) of fluid that is either received or discharged therefrom. More specifically, the driver 640 is mechanically linked to the plunger 638 so that controlled actuation thereof causes precise movements of the plunger 638 relative

to the barrel of the syringe. In one embodiment, the driver 640 is a stepper motor that can precisely control the distance that the plunger 638 is extended or retracted, which in turn corresponds to a precise volume of fluid being aspirated or discharged. Thus, each syringe 632, 634 has its own driver 640 so that the corresponding plunger 638 thereof can be precisely controlled and this permits the larger syringe 632 to handle large volumes of fluid, while the smaller syringe 634 handles smaller volumes of fluid. As is known, stepper motors can be controlled with a great degree of precision so that the stepper motor can be only be driven a small number of steps which corresponds to the plunger 638 being moves a very small distance. On the other hand, the stepper motor can be driven a large number of steps which results in the plunger 638 being moved a much greater distance. The drivers 640 are preferably a part of a larger automated system that is in communication with a master controller that serves to monitor and control the operation of the various components. For example, the master controller calculates the amount of fluid that is to be either discharged from or aspirated into the cannula 610 and the main conduit 620 and then determines the volume ratio as to how much fluid is to be associated with the first syringe 632 and how much fluid is to be associated with the second syringe 634. Based on these calculations and determinations, the controller instructs the drivers 640 to operate in a prescribed manner to ensure that the precise amount of volume of fluid is either discharged or aspirated into the main conduit 620 through the cannula 610.

The open end 636 of each syringe 632, 634 includes one or more connectors to fluidly couple the syringe 632, 634 with a source 650 of diluent and with the main conduit 620. In the illustrated embodiment, the first syringe 632 includes a first T connector 660 that is

coupled to the open end 636 and the second syringe 634 includes a second T connector 662 that is coupled to the open end 636 thereof. Each of the legs of the T connectors 660, 662 has an internal valve mechanism or the like 670 that is associated therewith so that each leg as well as the main body that leads to the syringe itself can either be open or closed and this action and setting is independent from the action at the other two conduit members of the connector. In other words and according to one preferred arrangement, the valve 670 is an internal valve assembly contained within the T connector body itself such that there is a separate valve element for each leg as well as a separate valve element for the main body. It will be appreciated that each of the legs and the main body defines a conduit section and therefore, it is desirable to be able to selectively permit or prevent flow of fluid in a particular conduit section.

In the illustrated embodiment, a first leg 661 of the first T connector 660 is connected to a first conduit 656 that is connected at its other end to the diluent source 650 and the second leg 663 of the first T connector 660 is connected to a connector conduit (tubing) 652 that is connected at its other end to the first leg of the second T connector 662 associated with the second syringe 634. A main body 665 of the first T connector 660 is mated with the open end 636 of the first syringe 632 and defines a flow path thereto. The connector conduit 652 thus serves to fluidly connect the first and second syringes 632, 634. As previously mentioned, the valve mechanism 670 is preferably of the type that includes three independently operable valve elements with one associated with one leg 661, one associated with the other leg 663 and one associated with the main body 665.

With respect to the second T connector 662, a first leg 667 is connected to the connector conduit 652 and a second leg 669 is connected to a second conduit 658 that is connected to the main conduit 620 or can actually be simply one end of the main conduit. A main body 671 of the second T connector 662 is mated with the open end 636 of the second syringe 634. As with the first T connector 660, the second T connector 662 includes an internal valve mechanism 670 that is preferably of the type that includes three independently operable valve elements with one associated with one leg 667, one associated with the other leg 669 and one associated with the main body 671.

The operation of the fluid pump system 630 is now described with reference to Figs. 10-13. If the operation to be performed is a reconstitution operation, the valve 670 associated with the second leg 669 is first closed so that the communication between the syringes and the main conduit 620 is restricted. The valve element 670 associated with first leg 661 of the T connector 660 is left open so that a prescribed amount of diluent can be received from the source 650. The valve element associated with the second leg 663 of the T connector 660 is initially closed so that the diluent from the diluent source 650 is initially drawn into the first syringe 630 and the valve element associated with the main body 665 is left open so that the diluent can flow into the first syringe 632. The driver 640 associated with the first syringe 632 is then actuated for a prescribed period of time resulting in the plunger 638 thereof being extended a prescribed distance. As previously mentioned, the distance that the driver 640 moves the corresponding plunger 638 is directly tied to the amount of fluid that is to be received within the syringe 632. The extension of the plunger 638 creates negative pressure in the first syringe 632, thereby causing diluent to be drawn therein. This is shown in Fig. 10.

Once the prescribed amount of fluid is received in the first syringe 632, the valve element associated with the main body 665 of the T connector 660 is closed and the valve element associated with the second leg 663 is open, thereby permitting flow from the first T connector 660 to the second T connector 662 as shown in Fig. 11. At the same time, the valve element associated with the first leg 667 and the main body 671 of the second T connector 662 are opened (with the valve element associated with the second leg 669 being kept closed).

The driver 640 associated with the second syringe 634 is then actuated for a prescribed period of time resulting in the plunger 638 thereof being extended a prescribed distance which results in a precise, prescribed amount of fluid being drawn into the second syringe 634. The extension of the plunger 638 creates negative pressure within the barrel of the second syringe 634 and since the second T connector 662 is in fluid communication with the diluent source 650 through the first T connector 660 and the connector conduit 652, diluent can be drawn directly into the second syringe 632. The diluent is not drawn into the first syringe 660 since the valve element associated with the main body 665 of the first T connector 660 is closed.

Thus, at this time, the first and second syringes 632, 634 hold in total at least a prescribed volume of diluent that corresponds to at least the precise volume that is to be discharged through the cannula 610 into the vial 60 to reconstitute the medication contained therein.

It will be understood that all of the conduits, including those leading from the source 650 and to the cannula are fully primed with diluent prior to performing any of the above operations.

To discharge the prescribed volume of diluent into the vial, the process is essentially reversed with the valve 670 associated with the first leg 661 of the T connector 660 is closed to prevent flow through the first conduit 656 from the diluent source 650. The valve element associated with the second leg 669 of the second T connector 662 is opened to permit fluid flow therethrough and into the second conduit 658 to the cannula 610. The diluent that is stored in the first and second syringes 632, 634 can be delivered to the second conduit 658 in a prescribed volume according to any number of different methods, including discharging the diluent from one of the syringes 632, 634 or discharging the diluent from both of the syringes 634. For purpose of illustration only, it is described that the diluent is drawn from both of the syringes 632, 634. This arrangement is shown in Fig. 12.

The diluent contained in the first syringe 632 can be introduced into the main conduit 620 by opening the valve associated with the second leg 663 and the main body 665 of the first T connector 660 as well as opening up the valve element associated with the first leg 667 of the second T connector 662, while the valve element associated with the main body 671 of the second T connector 662 remains closed. The valve element associated with the second leg 669 remains open. The driver 640 associated with the first syringe 632 is operated to retract the plunger 638 causing a positive pressure to be exerted and resulting in a volume of the stored diluent being discharged from the first syringe 632 into the connector conduit 652 and ultimately to the second conduit 658 which is in direct fluid communication with the

cannula 610. The entire volume of diluent that is needed for the reconstitution can be taken from the first syringe 632 or else a portion of the diluent is taken therefrom with an additional amount (fine tuning) to be taken from the second syringe 634.

When it is desired to withdraw diluent from the second syringe 634, the valve associated with the first leg 667 of the second T connector 662 is closed (thereby preventing fluid communication between the syringes 632, 634) and the valve associated with the main body 671 of the second T connector 662 is opened as shown in Fig. 13. The driver 640 associated with the second syringe 634 is then instructed to retract the plunger 638 causing a positive pressure to be exerted and resulting in the stored diluent being discharged from the second syringe 634 into the second conduit 658. Since the second conduit 658 and the main conduit 620 are fully primed, any new volume of diluent that is added to the second conduit 658 by one or both of the first and second syringes 632, 634 is discharged at the other end of the main conduit 620. The net result is that the prescribed amount of diluent that is needed to properly reconstitute the medication is delivered through the cannula 610 and into the vial 60. These processing steps are generally shown in Figs. 14-16 in which the cannula 610 pierces the septum of the vial and then delivers the diluent to the vial and then the cannula unit 590 and the vial gripper device 530 are inverted to cause agitation and mixing of the contents of the vial.

It will be understood that in some applications, only one of the first and second syringes 632, 634 may be needed to operate to first receive diluent from the diluent source 650 and then discharge the diluent into the main conduit 610.

After the medication in the vial 60 has been reconstituted as by inversion of the vial and mixing, as described herein, the fluid pump system 630 is then operated so that a

prescribed amount of medication is aspirated or otherwise drawn from the vial 60 through the cannula 610 and into the main conduit 620 as shown in Figs. 16-20. Before the fluid is aspirated into the main conduit 620, an air bubble is introduced into the main conduit 620 to serve as a buffer between the diluent contained in the conduit 620 to be discharged into one vial and the aspirated medication that is to be delivered and discharged into one syringe 10. It will be appreciated that the two fluids (diluent and prepared medication) can not be allowed to mix together in the conduit 620. The air bubble serves as an air cap in the tubing of the cannula and serves as an air block used between the fluid in the line (diluent) and the pulled medication. According to one exemplary embodiment, the air block is a 1/10 ml air block; however, this volume is merely exemplary and the size of the air block can be varied.

The aspiration operation is essentially the opposite of the above operation where the diluent is discharged into the vial 60. More specifically, the valve 670 associated with the first leg 661 of the first T connector 660 is closed and the valve associated with the second leg 669 of the second T connector 662 is opened to permit flow of the diluent in the main conduit into one or both of the syringes 632, 634. As previously mentioned, the second syringe 634 acts more as a means to fine tune the volume of the fluid that is either to be discharged or aspirated.

The drivers 640 associated with one or both of the first and second syringes 632, 634 are actuated for a prescribed period of time resulting in the plungers 638 thereof being extended a prescribed distance (which can be different from one another). As previously mentioned, the distance that the drivers 640 move the corresponding plungers 638 is directly tied to the volume of fluid that is to be received within the corresponding syringe 632, 634.

By extending one or both of the plungers 638 by means of the drivers 640, a negative pressure is created in the main conduit 620 as fluid is drawn into one or both of the syringes 632, 634. The creation of negative pressure within the main conduit 620 and the presence of the tip end of the cannula 610 within the medication translates into the medication being drawn into the cannula 610 and ultimately into the main conduit 620 with the air block being present therein to separate the pulled medication and the fluid in the line.

It will be appreciated that the aspiration process can be conducted so that fluid is aspirated into one of the syringes 632, 634 first and then later an additional amount of fluid can be aspirated into the other syringe 632, 634 by simply controlling whether the valves in the main bodies 665, 671 are open or closed. For example, if fluid is to be aspirated solely to the first syringe 632, then the valve elements associated with the first and second legs 667, 669 of the second T connector 662 and the valve element associated with the second leg 663 and main body 665 of the first T connector 660 are all open, while the valve elements associated with the first leg 661 of the T connector 660 and the main body 671 of the T connector 662 remain closed. After a sufficient volume of fluid has been aspirated into the first syringe 632 and it is desired to aspirate more fluid into the second syringe 634, then the valve element associated with the first leg 667 simply needs to be closed and then the driver 640 of the second syringe 634 is actuated to extend the plunger 638.

After aspirating the medication into the main conduit 620, the fluid transfer device 580 is rotated as is described below to position the cannula 610 relative to one syringe 10 that is nested within the rotary dial 130 as shown in Figs. 19 and 20. Since the plungers 638 are pulled a prescribed distance that directly translates into a predetermined amount of

medication being drawn into the main conduit 620, the plungers 638 are simply retracted (moved in the opposite direction) the same distance which results in a positive pressure being exerted on the fluid within the main conduit 620 and this causes the pulled medication to be discharged through the cannula 610 and into the syringe 10. During the aspiration operation and the subsequent discharge of the fluid, the valves are maintained at set positions so that the fluid can be discharged from the first and second syringes 632, 634. As the plungers 638 are retracted and the pulled medication is discharged, the air block continuously moves within the main conduit 620 toward the cannula 610. When all of the pulled (aspirated) medication is discharged, the air block is positioned at the end of the main conduit signifying that the complete pulled medication dose has been discharged; however, none of the diluent that is stored within the main conduit 620 is discharged into the syringe 10 since the fluid transfer device 580, and more particularly, the drivers 640 thereof, operates with such precision that only the prescribed medication that has been previously pulled into the main conduit 620 is discharged into the vial 60. The valve elements can be arranged so that the plungers can be retracted one at a time with only one valve element associated with the main bodies 665, 671 being open or the plungers can be operated at the same time.

It will be appreciated that the fluid transfer device 580 may need to make several aspirations and discharges of the medication into the vial 60 in order to inject the complete prescribed medication dosage into the vial 60. In other words, the cannula unit 590 can operate to first aspirate a prescribed amount of fluid into the main conduit 620 and then is operated so that it rotates over to and above one syringe 10 on the rotary dial 130, where one incremental dose amount is discharged into the vial 60. After the first incremental dose

amount is completely discharged into the syringe 10, the vertical base section 582 is rotated so that the cannula unit 590 is brought back the fluid transfer position where the fluid transfer device 582 is operated so that a second incremental dose amount is aspirated into the main conduit 620 in the manner described in detail hereinbefore. The vertical base section 582 is then rotated again so that the cannula unit 590 is brought back to the rotary dial 130 above the syringe 10 that contains the first incremental dose amount of medication. The cannula 610 is then lowered so that the cannula tip is placed within the interior of the syringe 10 and the cannula unit 590 (drivers 640) is operated so that the second incremental dose amount is discharged into the syringe 10. The process is repeated until the complete medication dose is transferred into the syringe 10.

In yet another embodiment shown in Fig. 21, the two syringes 632, 634 are not directly connected to one another but instead each of the syringes 632, 634 is directly fluidly connected to the diluent source 550 and the main conduit 620. More specifically, one leg of the T connector 660 of the first syringe 632 is coupled to a first conduit 656 that is connected at its other end to the diluent source 650 and the other leg of the connector 660 is coupled to a second conduit 658 that is connected at its other end to the main conduit 620. Similarly, one leg of the T connector 662 of the second syringe 634 is coupled to a first conduit 656 that is connected at its other end to the diluent source 650 and the other leg of the connector 662 is coupled to a second conduit 658 that is connected at its other end to the main conduit 620. In this manner, when it is desired to draw diluent from the diluent source 650, the respective drivers 640 are operated to cause the respective plungers 638 to be independently extended and depending upon the distance that each is extended, a prescribed volume of diluent is drawn into

the syringe. At this time, the valves 670 that are associated with the first conduits 658 are open, while those associated with the second conduits 658 are closed. As mentioned, the first syringe 632 typically draws a greater volume of diluent since the second syringe 634 is designed to fine tune and provide small increments of diluent to be added to the vial. Similarly, when an aspiration process is performed, the two valves associated with the first conduits 656 are closed and when the drivers 640 are operated to discharge or pump the aspirated medication, the valves 670 associated with the first conduits 656 remain closed.

Once the syringe 10 receives the complete prescribed medication dose, the vial 60 that is positioned at the fluid transfer position can either be (1) discarded or (2) it can be delivered to a holding station 700 where it is cataloged and held for additional future use. More specifically, the holding station 700 serves as a parking location where a vial that is not completely used can be used later in the preparation of a downstream syringe 10. In other words, the vials 60 that are stored at the holding station 700 are labeled as multi-use medications that can be reused. These multi-use vials 60 are fully reconstituted so that at the time of the next use, the medication is only aspirated from the vials 60 as opposed to having to first inject diluent to reconstitute the medication. The user can easily input into the database of the master controller which medications are multi-use medications and thus when the vial 60 is scanned and identified prior to being delivered to the fluid transfer position, the vial 60 is identified and marked as a multi-use medication and thus, once the entire medication dose transfer has been performed, the vial gripper device 530 is instructed to deliver the vial 60 to the holding station 700. Typically, multi-use medications are those medications that are more

expensive than other medications and also are those medications that are used in larger volumes (quantities) or are stored in larger containers and therefore come in large volumes.

The holding station 700 is simply a location where the multi-use vials can be easily stored. For example, the holding station 700 is preferably a shelf or even a cabinet that contains a flat surface for placing the vials 60. Preferably, there is a means for categorizing and inventorying the vials 60 that are placed at the holding station 700. For example, a grid with distinct coordinates can be created to make it easy to determine where each vial 60 is stored within the holding station 700.

Once the device 530 has positioned the gripper unit 540 at the proper location of the holding station 700, the gripper unit 540 is operated so that the arms thereof release the vial 60 at the proper location. The device 530 then returns back to its default position where it can then next be instructed to retrieve a new vial 60 from the pedestal 520.

If the vial 60 is not a multi-use medication, then the vial 60 at the fluid transfer position is discarded. When this occurs, the device 530 moves such that the vial 60 is positioned over a waste chute or receptacle and then the gripper unit 540 is actuated to cause the vial 60 to drop therefrom into the waste chute or receptacle. The device 530 then is ready to go and retrieve a new vial 60 that is positioned at the pedestal 520 for purposes of either reconstituting the medication or simply aspirating an amount of medication therefrom or a vial from the holding station 700 can be retrieved.

As previously mentioned, during the reconstitution process, it is often necessary or preferable to mix the medication beyond the mere inversion of the vial and therefore, the vial 60 can be further agitated using a mixing device or the like 710. In one embodiment, the

mixing device 710 is a vortex type mixer that has a top surface on which the vial 60 is placed and then upon actuation of the mixer, the vial 60 is vibrated or otherwise shaken to cause all of the solid medication to go into solution or cause the medication to be otherwise mixed. In yet another embodiment, the mixing device is a mechanical shaker device, such as those that are used to hold and shake paint cans. For example, the vial 60 can be placed on support surface of the shaker and then an adjustable hold down bar is manipulated so that it travels towards the vial and engages the vial at an end opposite the support surface. Once the vial 60 is securely captured between these two members, the shaker device is actuated resulting in the vial 60 being shaken to agitate the medication and ensure that all of the medication properly goes into solution. This type of mixing device can also be configured so that it is in the form of a robotic arm that holds the vial by means of gripper members (fingers) and is operatively connected to a motor or the like which serves to rapidly move the arm in a back and forth manner to cause mixing of the medication.

As briefly mentioned before, the entire system 100 is integrated and automated and also utilizes a database for storing identifying data, mixing instructions, and other information to assist in the preparation of the medication. There are also a number of safety features and check locations to make sure that the medication preparation is proceeding as it should.

For example, the database includes identifying information so that each vial 60 and syringe 10 can be carefully kept track of during each step of the process. For example, a scanner 720 and the photoimaging equipment serve to positively identify the vial 60 that is delivered from the drug storage 110. Typically, the user will enter one or more medication

preparation orders where the system 100 is instructed to prepare one or more syringes that contain specific medication. Based on this entered information or on a stored medication preparation order that is retrieved from a database, the vial master controller determines at which location in the cabinet the correct vial 60 is located. That vial 60 is then removed using a robotic gripper device (not shown) and is then placed on the conveyor belt 111 and delivered to the mechanism 510 pivots upright so that the vial 60 is moved a vertical position relative to the ground and is held in an upright manner and is then delivered to the rotatable pedestal 520. At the pedestal 520, the vial 60 is scanned to attempt to positively identify the vial 60 and if the scanned identifying information matches the stored information, the vial 60 is permitted to proceed to the next station. Otherwise, the vial 60 is discarded.

Once the vial 60 is confirmed to be the right vial it proceeds to the fluid transfer position. The master controller serves to precisely calculate how the fluid transfer operation is to be performed and then monitors the fluid transfer operations as it is occurring. More specifically, the master controller first determines the steps necessary to undertake in order to perform the reconstitution operation. Most often during a reconstitution operation, the vial 60 that is retrieved from the drug storage 110 contains a certain amount of medication in the solid form. In order to properly reconstitute the medication, it is necessary to know what the desired concentration of the resulting medication is to be since this determines how much diluent is to be added to the vial 60. Thus, one piece of information that the user is initially asked to enter is the concentration of the medication that is to be delivered to the patient as well as the amount that is to be delivered. Based on the desired concentration of the medication, the master controller is able to calculate how much diluent is to be added to the

solid medication in the vial 60 to fully reconstitute the medication. Moreover, the database also preferably includes instructions as to the mixing process in that the mixing device is linked to and is in communication with the master controller so that the time that the mixing device is operated is stored in the database such that once the user inputs the medication that is to be prepared and once the vial 60 is scanned and identified, the system (master controller or CPU thereof) determines the correct of time that the vial 60 is to be shaken to ensure that all of the medication goes into solution.

Once the master controller determines and instructs the working components on how the reconstitution operation should proceed, the master controller also calculates and prepares instructions on how many distinct fluid transfers are necessary to deliver the prescribed amount of medication from the vial 60 to the syringe 10. In other words, the cannula unit 590 may not be able to fully aspirate the total amount of medication from the vial 60 in one operation and therefore, the master controller determines how many transfer are needed and also the appropriate volume of each aspiration so that the sum of the aspiration amounts is equal to the amount of medication that is to be delivered to the syringe 10. Thus when multiple aspiration/discharge steps are required, the master controller instructs and controls the operation of the drivers 640 so that the precise amounts of medication are aspirated and then discharged into the syringe 10. As previously described, the syringe drivers 640 retract and advance at the right levels to cause the proper dose amount of the medication to be first aspirated from the vial and then discharged into the syringe. This process is repeated as necessary until the correct dose amount is present in the syringe 10 in accordance with the initial inputted instructions of the user.

After transferring the proper precise amount of medication to one syringe 10, the master controller instructs the rotary dial to move forward in an indexed manner so that the next empty syringe 10 is brought into the fluid transfer position. The cannula 610 is also preferably cleaned after each medication dose transfer is completed so as to permit the cannula 610 to be reused. There are a number of different techniques that can be used to clean the cannula 610 between each medication transfer operation. For example, the cleaning equipment and techniques described in commonly assigned U.S. patent No. 6,616,771 and U.S. patent application serial No. 10/457,898 (both of which are hereby incorporated by reference in their entireties) are both suitable for use in the cleaning of the cannula 610.

In one embodiment, the cannula 610 is rotated and positioned so that the needle of the cannula 610 is lowered into a bath so that fluid is expelled between the inside hubs of the syringe 10 for cleaning of the interior components of the cannula 610. The cannula 610 is then preferably dipped into a bath or reservoir to clean the outside of the cannula 610. In this manner, the cannula 610 can be fully cleaned and ready for a next use without the need for replacement of the cannula 610, which can be quite a costly endeavor.

In yet another embodiment illustrated in Figs. 22-24, a medication source 730, such as a bag that is filled with liquid medication that has already been properly reconstituted, is connected to an input portion of a peristaltic pump 732 by means of a first conduit section 740. A second conduit section 742 is connected to an output port of the pump 732 and terminates in a connector 744. The connector 744 is of the type that is configured to hermetically seal with an open barrel tip of the syringe 10 that is nested within the rotary dial 130 and is marked to receive medication. The connector 744 typically includes a conduit

member 745 (tubing) that is surrounded by a skirt member or the like 747 that mates with the outer hub of the syringe barrel. A flange or diaphragm 749 can be provided as shown in Fig. 24 for hermetically sealing with the syringe barrel (outer hub).

In commonly assigned U.S. patent application serial No. 10/457,066 (which is hereby incorporated by reference in its entirety), it is described how the plunger 50 of the syringe 10 can be extended with precision to a prescribed distance. In that application, the plunger 50 is extended to create a precise volume in the barrel that is to receive the medication that is injected therein at a downstream location. However, it will be appreciated that the action of extending the plunger 50 can serve more than this purpose since the extension of the plunger 50 creates negative pressure within the syringe barrel and thus can serve to draw a fluid therein. For example, once the connector 744 is sealingly mated with the open syringe tip end, the medication source 730 is fluidly connected to the syringe 10 and thus can be drawn into the syringe barrel by means of the extension of the plunger 50. In other words, the plunger 50 is pulled a precise distance that results in the correct size cavity being opened up in the barrel for receiving the fluid but also the extension of the plunger creates enough negative pressure to cause the medication to be drawn into the syringe barrel. This is thus an alternative means for withdrawing the proper amount of medication from a member (in this case the source 730) and transferring the desired, precise amount of medication to the syringe 10. The operation of this alternative embodiment can be referred to as operating the system in reservoir mode. One advantage of this embodiment is that multiple syringe drivers are not needed to pump the medication into the syringe 10 but rather the drawing action is created

right at the rotary dial 130. This design is thus fairly simple; however, it is not suitable for instances where drug reconstitution is necessary.

In yet another embodiment, a detection station 800 is provided, as shown in Fig. 9, and serves as a vial orientation detector that is an automated means for determining whether the vial 60 is in correct orientation throughout one or more stages of the operation. For example, the detection station 800 includes a detector or the like 810 which determines whether the vial is an upright position or is in the opposite downright position. The orientation of the vial 60 is very important as the vial 60 is moved from one station to the next since if the vial 60 is orientated wrong, this can lead to damage or destruction of certain components of the equipment. According to one embodiment, one detector 810 is positioned near the pedestal 520 and it serves to detect the state of the vial 60 before it is introduced into the decapper station 550 since if the vial 60 is introduced in the wrong state, this will possibly lead to damaging the decapper equipment and certainly will not result in the vial cap being removed. Typically and during a normal operation, the vial 60 stands upright on the pedestal 520 and then the vial gripper device 530 grips and inverts the vial 60 as it delivers it to the decapper station 550. Thus, the detector 810 can be configured to either detect the vial 60 being in the proper upright position on the pedestal 520 or it can detect the vial 60 being inverted after it has been removed from the pedestal 520.

There are a number of different types of detectors 810 that are suitable for use in the present application so long as the detector 810 functions in the aforementioned manner. For example, the detector 810 can be of the type that reads a marker or detects the absence thereof that is placed on the vial 60. In one embodiment shown in Fig. 27, the vial 60 includes

or total destruction of the tip end of the cannula 610. The cannula unit itself can be very costly and thus, it is desirable to have a detector means associated upstream or at the fluid transfer station to ensure that the vial 60 is in its proper upright position. If the detector fails to detect that the vial 60 is in the desired upright position, then the cannula unit 590 is not activated and the vial gripper device 530 is instructed to bring the held vial 60 to a station where it is discarded into a collection receptacle and the process is started over again resulting in the vial gripper device 530 moving to a default position.

While the above described detector 810 reads and detects changes in magnetic fields, any number of other types of detectors can be used. For example and according to the embodiment shown in Fig. 28, the detector 810 can be an optical reader that detects the presence or absence of an optical marker 813 (ring shaped optically detectable member) that is formed on the vial 60. Once the detector 810 reads or after a period of time passes in which the detector 810 does not detect the marker, then an appropriate signal is generated and delivered to the master controller that in turn controls the advancement or discarding of the syringe 10. It will be appreciated that there are other types of detectors 810 that can be incorporated into the present invention for the purpose of detecting the orientation of the vial 60. For example, the detector 810 can be a reader and the vial 60 can include a scannable tag that is attached thereto at one location. The detector 810 continuously reads as by emitting a beam or the like and once and if the scannable tag passes through the beam, the detector reads the tag and generates a control signal indicating that the vial is in the proper orientation and should be advanced to the next station. In other words, the information encoded on the scannable tag is not important but what is important is that the detector only can read this

information and take affirmative action, such as generating to the control signal, when the vial is in the proper orientation. If the vial is not in its proper orientation, then the scannable tag will not pass through the beam and no control signal is generated and thereby, the vial 60 is not advanced to the next station.

It will also be appreciated that the location of the detector 810 can be varied and the above described locations are merely exemplary in nature and not limiting of the present invention. The detector 810 is preferably located at any position where it is desirable for the position (orientation) of the vial 60 to be determined and monitored. However, preferred locations include those previously described where the vial 60 is about to be introduced to a station where an operation is to be performed on the vial 60.

Prior to its using another drug, the cannula 610 is cleaned using conventional techniques, such as those described in the previously incorporated patents and patent applications.

After the medication is aspirated into the barrel 20, the dial 130 is advanced so that the filled syringe 10 is delivered to the sixth station 180 (Fig. 2). For example, the dial 130 is preferably advanced so that the filled syringe 10 is delivered to a station where the removed tip cap 40 is replaced back onto the barrel tip 28 by a device 900. Referring to Figs. 25 and 26, the device 900 can be similar or identical to the device 300 that removes the tip cap 40 from the barrel tip 28 at an earlier station or the device 900 can be different from the device 300 so long as the device 900 is configured to grasp the tip cap 40 from the post 161 and then place the tip cap 40 back on the barrel tip 28.

For purpose of illustration and simplicity, the device 900 will be described as being of the same type as device 300. The automated device 900 is a robotic device and preferably, the automated device 900 is a linear actuator with a gripper. The device 900 has a vertical base 910 which is adjustable in at least several directions. For example, the vertical base 910 has an independent reach (y axis) and vertical axis (x axis) which provides part of the flexibility and motion control that is desirable for the device 900. The vertical base 910 has an upper end 912 and an opposing lower end 914 which is operatively coupled to other movable components to permit the vertical base 910 to move in an up/down direction along the x axis and in lateral directions along the y axis. The upper end 912 is connected to a horizontal support member 920 that extends outwardly away from the vertical base 910. In one exemplary embodiment, the lower end 614 is disposed between two support beams that are part of a robotic device and are moved in a number of different directions, including along the x axis and the y axis.

A block member 930 is connected to the horizontal support member 920 and more specifically, the block member 930 is disposed on an underside of the horizontal support member 920 so that it is spaced away from the vertical base 910. The exemplary block member 930 has a block-like shape and is connected to the underside of the horizontal support member 920 by one or more connectors that can be in the form of support columns, etc.

The device 900 has first and second positionable gripping arms 940 which are adjustable in at least one direction and which are coupled to and extend downwardly from the block member 930. For example, each of the gripping arms 940 is movable at least in a direction along the y axis which provides the flexibility and motion control that is desirable in

the present system 100. The gripping arms 940 are programmed to work together in tandem so that both arms 940 are driven to the same location and the same time.

The block member 930 can house some of the electronic or hydraulic components and the like that permit the gripping arms 940 to move between the open and closed positions. The coupling between the block member 930 and the gripping arms 940 is such that the gripping arms 940 have the necessary degree of movement to permit the opening and closing thereof.

Each of the gripping arms 940 is a generally L-shaped member that is formed of a vertical section 942 and a horizontal gripping section (not shown) that extends outwardly from one end of the vertical section 942. The gripping section has a cut-out or notch 360 (Fig. 3) formed therein for receiving and gripping a section of the barrel 20 of the syringe 10. Accordingly, the notch has a complementary shape as the shape of the barrel 20. One exemplary notch has a generally semi-circular shape and it seats against approximately $\frac{1}{2}$ of the outer circumferential surface of the syringe barrel 20. By being movable along at least the y axis, the gripping arms 940 can be positioned between an open position in which the opposing gripping sections of the arms 940 are spaced apart from one another a sufficient distance to permit the tip cap 40 to be received therebetween.

In the closed position, the gripping sections of the arms 940 are brought together so that they either seat against one another or are in very close proximity to one another. When the gripping sections come together in the closed position, the notches define a complete circular opening that has a diameter about equal to or slightly less than the diameter

of the base section 41 of the tip cap 40, thereby permitting the tip cap 40 to nest within the gripping sections 944.

In a first open position of the gripping arms 940, the gripping sections being spaced sufficiently from one another so as to permit the tip cap 40 to be freely disposed between the gripping sections. Using a control unit 950 (e.g., a programmable actuator, microprocessor, etc.), the gripping arms 940 are driven to the first position shown in Fig. 14. The control unit 950 instructs the device 900 to perform an operation where the tip cap 40 resting on the post 161 is gripped and removed by the device 900. When such an operation is performed, the vertical base 910 is driven inwardly toward the dial 130 and upwardly so that the gripping arms 940 are positioned over the tip cap 40 that is disposed on top of the post 161. The vertical base 910 is then driven downward until the gripping arms 940 are disposed around the tip cap 40. In other words, the tip cap 40 is disposed between the gripping section of the opposing arms 940 and more specifically, the gripping sections 944 are disposed adjacent the base section 41 of the tip cap 40 underneath the flange 43 with the notches being aligned with the outer surface of the base section 41. An actuator or the like of the device 900 is then activated causing the gripping arms 940 to move inwardly toward one another until the gripping sections 944 seat against the outer surface of the base section 41 of the tip cap 40. Preferably, a hydraulic or pneumatic system can be used to move the gripping arms 940 between their relative positions. In this closed position, the gripping arms 940 apply a force against the base section 41 so that the tip cap 40 is securely held by the gripping sections. When the gripping arms 940 are driven to the closed position, the gripping sections may seat

It will be appreciated by persons skilled in the art that the present invention is not limited to the embodiments described thus far with reference to the accompanying drawings; rather the present invention is limited only by the following claims.
